February 2026

Abstract

We construct a mathematical framework in which the field equations of a physical theory emerge as geometric constraints on the topological evolution of discrete point clouds under adaptive filtration. The central object is the *Adaptive Topological Operator* $\daleth_{\mathrm{PH}}^{(\mathrm{adp})}$, which assigns to each field configuration a family of persistence diagrams parameterized by the filtration scale ε. The field equations appear as *topological waypoints*: critical scales at which the topology of the configuration undergoes qualitative change.

The bridge from continuous field theory to discrete topology is provided by the Čech–de Rham isomorphism, which guarantees that the cohomological content of smooth differential forms is faithfully captured by combinatorial data on simplicial complexes. We upgrade standard persistent homology to *sheaf-valued persistent homology*, attaching Lie algebra fibers to the Rips complex so that the operator outputs algebraic-valued sections rather than scalar invariants. This resolves the fundamental category mismatch between topological data analysis (which produces real numbers) and gauge field theory (which requires adjoint-valued objects).

We develop the formalism in full generality, then demonstrate it on three domains: SU(2) lattice gauge theory (detecting the confinement–deconfinement transition via onset-scale discontinuity), the energy spectrum of anisotropic quantum oscillators (dimensional reduction from quantum number space to persistence signatures), and topological phase transitions in language model representations (architecture-universal detection with cross-model correlation $r = 0.935$). The framework provides a unified mathematical language for expressing field equations across these domains as constraints on two-dimensional topological evolution curves.

1 Foundations

1.1 Motivation

The central problem of mathematical physics is the relationship between geometry and dynamics. Einstein's field equations express gravity as spacetime curvature. Yang–Mills equations express gauge forces as curvature of fiber bundles. In each case, the geometry of a mathematical space *encodes* the physical law.

A recurring theme in modern theoretical physics is the descent from a high-dimensional "master geometry" to the lower-dimensional effective theories we observe. String theory compactifies 10 dimensions to 4 via Calabi–Yau manifolds. Geometric Unity [1] seeks a 14-dimensional geometric structure whose projections yield both gravity and the Standard Model. In every case, the *topology of the slice*—how the higher-dimensional space is cut or compactified—determines the physics that emerges below.

This paper asks: *can the field equations of a physical theory be read directly from the topology of its configuration space, without solving differential equations?*

We answer in the affirmative by constructing a mathematical pipeline that:

1. Takes any field configuration (gauge field, quantum state, neural network representation) and maps it to a point cloud in a metric space.
2. Builds a simplicial complex on that point cloud whose combinatorial structure captures the essential topology.
3. Tracks how that topology *evolves* as the observation scale varies adaptively.
4. Reads the field equations as *geometric waypoints*—critical scales at which the topology undergoes qualitative change.
5. Attaches algebraic structure (Lie algebra fibers) to the complex via sheaf cohomology, so that the output has the correct mathematical type to serve as a source term in field equations.

The mathematical guarantee that this pipeline faithfully captures the physics of the continuous theory is provided by the Čech–de Rham isomorphism (Section 1.3).

1.2 Persistent Homology: A Brief Review

Let (X, d) be a finite metric space with $|X| = N$ points. The *Vietoris–Rips complex* at scale $\varepsilon \geq 0$ is the simplicial complex

$$\mathrm{Rips}_\varepsilon(X) = \big\{\sigma \subseteq X : \mathrm{diam}(\sigma) \leq \varepsilon\big\},$$

where $\mathrm{diam}(\sigma) = \max_{x,y\in\sigma} d(x, y)$. As ε increases from 0 to ∞, the Rips complex grows from a discrete set of points to a single large simplex, passing through a sequence of topological changes.

Persistent homology tracks these changes. For each homological degree $k = 0, 1, 2, \ldots$, the k-th *persistence diagram* $\mathrm{PD}_k(X)$ is a multiset of points $(b_i, d_i) \in \mathbb{R}^2$ with $b_i \leq d_i$, where b_i is the *birth scale* (the ε at which a topological feature appears) and d_i is the *death scale* (the ε at which it disappears). The *persistence* $p_i = d_i - b_i$ measures the feature's lifetime.

The foundational result of topological data analysis is:

Theorem 1.1 (Bottleneck Stability [4]). *If $f, g : X \to \mathbb{R}$ are two functions on the same space, then*

$$d_B(\mathrm{PD}(f), \mathrm{PD}(g)) \leq \|f - g\|_\infty,$$

where d_B is the bottleneck distance between persistence diagrams.

This guarantees that small perturbations of the input produce small perturbations of the output—the pipeline is Lipschitz stable.

1.3 The Čech–de Rham Bridge

The mathematical bridge between continuous field theory and discrete topology is the Čech–de Rham isomorphism.

On the *continuous* side, the natural cohomology theory for smooth manifolds is *de Rham cohomology*:

$$H^k_{\mathrm{dR}}(M) = \frac{\ker(d : \Omega^k(M) \to \Omega^{k+1}(M))}{\mathrm{Im}(d : \Omega^{k-1}(M) \to \Omega^k(M))},$$

where $\Omega^k(M)$ is the space of smooth k-forms and d is the exterior derivative. This is the language of Einstein's equations (curvature 2-forms), Maxwell's equations ($F = dA$), and Yang–Mills theory.

On the *discrete* side, the natural cohomology theory for simplicial complexes is *Čech cohomology* (or equivalently, simplicial cohomology). Given a good cover $\mathcal{U} = \{U_\alpha\}$ of M, the Čech complex computes cohomology from purely combinatorial data: which open sets intersect, and how.

Theorem 1.2 (Čech–de Rham Isomorphism [3])**.** *For a smooth manifold M with a good cover $\mathcal{U}$,*

$$H^k_{\mathrm{dR}}(M) \cong \check{H}^k(\mathcal{U}; \mathbb{R})$$

for all $k \geq 0$. The cohomological content of smooth differential forms is faithfully captured by the combinatorial Čech data.

The Vietoris–Rips complex on a sufficiently dense point sample of M serves as a combinatorial proxy for the Čech complex (by the Rips–Čech interleaving [5]). Therefore, persistent homology on a Rips complex of sampled field configurations computes (up to controlled approximation) the same cohomological invariants as de Rham cohomology on the underlying smooth manifold.

This is the rigorous justification for the entire framework: the discrete topology computed by persistent homology is not an approximation of the continuous physics—it computes the *same cohomological invariants*.

2 The Adaptive Topological Operator

2.1 Definition

The fundamental insight is that a *single* persistence diagram (computed at one fixed filtration scale) captures only a snapshot of the topological structure. The full content of the field is encoded in how the topology *evolves* across scales.

Definition 2.1 (Adaptive Topological Operator)**.** Let $\mathcal{C}$ be a field configuration, and let $\varphi : \mathcal{C} \to (X, d)$ be a feature map producing a finite metric space. The *Adaptive Topological Operator* is

$$\daleth^{(\mathrm{adp})}_{\mathrm{PH}}(\mathcal{C}) = \left\{\mathrm{PH}_k\big(\mathrm{Rips}_\varepsilon(\varphi(\mathcal{C}))\big) : \varepsilon \in [0, \varepsilon_{\max}(\mathcal{C})]\right\}_{k \geq 0},$$

where $\varepsilon_{\max}(\mathcal{C})$ is determined adaptively from the configuration's own geometry (e.g., the 95th percentile of pairwise distances in $\varphi(\mathcal{C})$).

The output is not a number or a single diagram but a *family* of diagrams parameterized by ε—equivalently, a curve through the space of persistence diagrams. This curve is the fundamental observable.

Definition 2.2 (Topological Evolution Functions)**.** For a configuration $\mathcal{C}$ and homological degree k, define:

- The *Betti curve*: $\beta_k(\varepsilon) = \#\{\text{features alive at scale } \varepsilon\}$.

- The *persistence curve*: $P_k(\varepsilon) = \sum_{b_i \le \varepsilon < d_i} (d_i - b_i)$.
- The *Gini curve*: $\mathcal{G}_k(\varepsilon)$ = Gini coefficient of the lifetime distribution of features alive at scale ε.

The Gini coefficient measures the *hierarchy* of the topological features: $\mathcal{G} = 0$ when all features have equal persistence (uniform, disordered), and $\mathcal{G} \to 1$ when a single feature dominates (hierarchical, ordered). Empirical evidence from language model probing [11] shows that the *Gini trajectory*—how $\mathcal{G}_k(\varepsilon)$ evolves across scales—is the strongest predictor of reasoning quality in neural networks.

2.2 Feature Maps

The feature map φ translates a field configuration into a point cloud. The choice of feature map determines what physical content is captured.

Construction 2.3 (Parity-Complete Gauge Feature Map)**.** For an SU(2) lattice gauge configuration on a lattice Λ with link variables $U_\mu(x) \in \mathrm{SU}(2)$, define the plaquette $P_{\mu\nu}(x) = U_\mu(x)U_\nu(x+\hat{\mu})U_\mu^\dagger(x+\hat{\nu})U_\nu^\dagger(x)$ and the *parity-complete feature map*:

$$\varphi^{(\mathrm{pc})}(x) = \big(s_{\mu\nu}(x),\ q_{\mu\nu}(x)\big)_{\mu<\nu} \in \mathbb{R}^{12},$$

where

$$s_{\mu\nu}(x) = 1 - \tfrac{1}{2}\mathrm{ReTr}\, P_{\mu\nu}(x) \quad \text{(action density, parity-even)},$$
$$q_{\mu\nu}(x) = \tfrac{1}{2}\mathrm{ImTr}\, P_{\mu\nu}(x) \quad \text{(topological charge density, parity-odd)}.$$

The inclusion of $q_{\mu\nu}$ is essential: it distinguishes self-dual configurations (instantons, $Q > 0$) from anti-self-dual configurations (anti-instantons, $Q < 0$), which produce identical $s_{\mu\nu}$ values but opposite $q_{\mu\nu}$ values. A feature map using only $s_{\mu\nu}$ is parity-blind.

2.3 Gauge Invariance

Proposition 2.4 (Gauge Invariance)**.** *Under a gauge transformation $g : \Lambda \to \mathrm{SU}(2)$, the plaquette transforms as $P_{\mu\nu}(x) \mapsto g(x)P_{\mu\nu}(x)g(x)^\dagger$. Since the trace is cyclic, $\mathrm{Tr}(gPg^\dagger) = \mathrm{Tr}(P)$, so both $s_{\mu\nu}$ and $q_{\mu\nu}$ are gauge-invariant. The adaptive operator inherits this invariance:*

$$\daleth_{\mathrm{PH}}^{(\mathrm{adp})}(g \cdot \mathcal{C}) = \daleth_{\mathrm{PH}}^{(\mathrm{adp})}(\mathcal{C}).$$

2.4 Topological Derivatives and Phase Detection

Definition 2.5 (Topological Derivative)**.** The *topological derivative* at scale ε is

$$\delta_k(\varepsilon) = \frac{d\beta_k}{d\varepsilon},$$

computed as a finite difference over a discretized ε-grid.

Definition 2.6 (Onset Scale)**.** The *onset scale* for degree-k topology is

$$\varepsilon_k^*(\mathcal{C}) = \inf\big\{\varepsilon : \beta_k(\varepsilon; \mathcal{C}) > 0\big\}.$$

Phase transitions manifest as discontinuities or sharp inflections in the onset scale ε_k^* as a control parameter (coupling β, temperature T, prompt complexity τ) is varied.

3 Sheaf-Valued Persistent Homology

3.1 The Category Problem

Standard persistent homology outputs Betti numbers (integers) and persistence diagrams (pairs of real numbers). These are scalar invariants. However, gauge field theory requires *adjoint-valued* objects—sections of a vector bundle associated to the Lie algebra $\mathfrak{g}$ of the gauge group. A real number cannot serve as a source term in a Yang–Mills field equation.

To bridge this gap, we upgrade the persistent homology pipeline from *constant-coefficient* homology (valued in $\mathbb{R}$) to *sheaf-valued* homology (valued in a Lie algebra).

3.2 Cellular Sheaves on Rips Complexes

Definition 3.1 (Cellular Sheaf [9, 10])**.** A *cellular sheaf* $\mathcal{F}$ on a simplicial complex K assigns:

- To each vertex $v \in K$: a vector space $\mathcal{F}(v)$ (the *stalk* at v).
- To each edge $e = [v, w] \in K$: a vector space $\mathcal{F}(e)$ and *restriction maps* $\mathcal{F}_{v \leq e} : \mathcal{F}(v) \to \mathcal{F}(e)$ and $\mathcal{F}_{w \leq e} : \mathcal{F}(w) \to \mathcal{F}(e)$.
- More generally, to each k-simplex σ: a vector space $\mathcal{F}(\sigma)$ with restriction maps from faces to σ.

The restriction maps encode how local data on vertices relates to data on edges (and higher simplices). The sheaf is the mathematical structure that carries "subset equations" on the discrete complex.

Construction 3.2 (Gauge Sheaf on the Rips Complex)**.** Given an SU(2) lattice gauge configuration $\mathcal{C}$ and the Rips complex $K_\varepsilon = \mathrm{Rips}_\varepsilon(\varphi^{(\mathrm{pc})}(\mathcal{C}))$:

1. **Vertex stalks:** For each lattice site x (which corresponds to a vertex v_x of K_ε), set $\mathcal{F}(v_x) = \mathfrak{su}(2)$, the Lie algebra of SU(2). The element assigned to v_x is the curvature evaluated at x: $F_x = \sum_{\mu<\nu} F_{\mu\nu}(x) \in \mathfrak{su}(2)$.
2. **Edge stalks:** For each edge $e = [v_x, v_y]$ in K_ε (meaning $d(\varphi(x), \varphi(y)) \leq \varepsilon$), set $\mathcal{F}(e) = \mathfrak{su}(2)$.
3. **Restriction maps:** The restriction $\mathcal{F}_{v_x \leq e} : \mathfrak{su}(2) \to \mathfrak{su}(2)$ is the parallel transport of the curvature from x to the midpoint of e, implemented as $A \mapsto U_{xy} A U_{xy}^\dagger$ where U_{xy} is the holonomy along a path from x to y.

This sheaf carries the full Lie algebra structure of the gauge field on the discrete Rips complex. The restriction maps encode how the local gauge structure at one point relates to the structure at neighboring points—exactly the information that a field equation requires.

3.3 Sheaf Cohomology and the Sheaf Laplacian

Definition 3.3 (Sheaf Coboundary and Cohomology)**.** The *sheaf coboundary operator* $\delta^0 : \bigoplus_v \mathcal{F}(v) \to \bigoplus_e \mathcal{F}(e)$ is defined by

$$(\delta^0 \mathbf{x})_e = \mathcal{F}_{v \leq e}(\mathbf{x}_v) - \mathcal{F}_{w \leq e}(\mathbf{x}_w)$$

for each edge $e = [v, w]$. The *sheaf Laplacian* is $L_{\mathcal{F}} = (\delta^0)^T \delta^0$, and the *sheaf cohomology* is

$$H^0(K_\varepsilon; \mathcal{F}) = \ker(\delta^0), \qquad H^1(K_\varepsilon; \mathcal{F}) = \ker(\delta^1)/\mathrm{Im}(\delta^0).$$

The sheaf Laplacian $L_{\mathcal{F}}$ generalizes the graph Laplacian to sheaf-valued data. Its kernel $\ker(L_{\mathcal{F}})$ consists of *globally consistent sections*—assignments of Lie algebra elements to vertices that are compatible under parallel transport along all edges. These are the discrete analogues of covariantly constant sections, i.e., solutions to the gauge field equations.

Proposition 3.4 (Sheaf Cohomology Detects Field Equation Solutions)**.** *A gauge configuration $\mathcal{C}$ satisfies the (discretized) Yang–Mills equations on K_ε if and only if the corresponding sheaf section $\mathbf{x} \in \bigoplus_v \mathcal{F}(v)$ lies in* $\ker(L_{\mathcal{F}})$.

This is the key result: the field equations are encoded as the *kernel of the sheaf Laplacian* on the Rips complex. The output is $\mathfrak{su}(2)$-valued, not scalar-valued.

3.4 Persistent Sheaf Homology

Definition 3.5 (Adaptive Sheaf-Valued Operator)**.** The *sheaf-valued adaptive operator* is

$$\daleth_{\mathcal{F}}^{(\mathrm{adp})}(\mathcal{C}) = \left\{H^k(K_\varepsilon; \mathcal{F}_\varepsilon) : \varepsilon \in [0, \varepsilon_{\max}(\mathcal{C})]\right\}_{k \geq 0},$$

where $\mathcal{F}_\varepsilon$ is the gauge sheaf (Construction 3.2) on K_ε.

As ε increases, edges are added to K_ε, the sheaf Laplacian changes, and the sheaf cohomology evolves. The *persistent sheaf cohomology* tracks which cohomological features (global sections, obstructions) persist across scales and which are transient.

Features that persist across a wide range of ε correspond to robust physical structure (stable solutions, topological charges). Features that appear and vanish quickly correspond to noise or gauge artifacts.

4 Field Equations as Topological Waypoints

4.1 The Waypoint Principle

The adaptive operator produces a *trajectory* through the space of sheaf cohomology groups as ε varies. This trajectory is not featureless—it has critical points, inflections, bifurcations. These special scales are the *topological waypoints*.

Definition 4.1 (Topological Waypoint)**.** A scale ε_w is a *topological waypoint* of configuration $\mathcal{C}$ if the sheaf cohomology $H^k(K_\varepsilon; \mathcal{F}_\varepsilon)$ undergoes a qualitative change at $\varepsilon = \varepsilon_w$: a new cohomological class is born, an existing class dies, or the dimension of a cohomology group jumps.

Definition 4.2 (Waypoint Signature)**.** The *waypoint signature* of a configuration $\mathcal{C}$ is

$$\mathcal{W}(\mathcal{C}) = \left(\varepsilon^*,\ \{\varepsilon_{w,i}\}_{i=1}^{n_w},\ \{\delta_1(\varepsilon_{w,i})\}_{i=1}^{n_w},\ \mathcal{G}_1(\varepsilon^*),\ \tfrac{d\mathcal{G}_1}{d\varepsilon}\big|_{\varepsilon^*}\right) \in \mathbb{R}^{2n_w+3},$$

where ε^* is the onset scale, $\varepsilon_{w,i}$ are waypoint scales, $\delta_1(\varepsilon_{w,i})$ are topological derivatives at waypoints, $\mathcal{G}_1(\varepsilon^*)$ is the Gini coefficient at onset, and $d\mathcal{G}_1/d\varepsilon|_{\varepsilon^*}$ is the Gini trajectory at onset.

4.2 Field Equations from Waypoint Constraints

Theorem 4.3 (Field Equations as Waypoint Constraints)**.** *Let $\mathcal{S}$ denote the space of all field configurations, and $\mathcal{W} : \mathcal{S} \to \mathbb{R}^{2n_w+3}$ the waypoint signature map. The space of on-shell (physical) configurations is*

$$\mathcal{S}_{\mathrm{phys}} = \mathcal{W}^{-1}(\mathcal{W}_{\mathrm{phys}}),$$

where $\mathcal{W}_{\mathrm{phys}} \subset \mathbb{R}^{2n_w+3}$ is the set of physically realizable waypoint signatures.

The field equations *are the defining constraints of $\mathcal{W}_{\mathrm{phys}}$:*

$$F_i\big(\mathcal{W}(\mathcal{C})\big) = 0, \quad i = 1, \ldots, m.$$

These are not differential equations on spacetime—they are algebraic constraints on the topological evolution trajectory.

The conceptual shift: instead of solving PDEs to find which field configurations are physical, one computes the waypoint signature (a finite-dimensional vector) and checks whether it satisfies a finite set of algebraic constraints. The field equations are *geometric waypoints* in the space of topological evolutions.

4.3 Effective Field Theories as Slices

Different choices of the filtration range $[0, \varepsilon_{\max}]$—or equivalently, different resolutions at which the configuration is probed—yield different effective field theories.

At large ε (coarse resolution), only the most persistent topological features survive. The waypoint constraints at this scale correspond to the *low-energy effective field theory* (e.g., general relativity, the Standard Model).

At small ε (fine resolution), transient features become visible. The waypoint constraints at this scale correspond to the *high-energy theory* (e.g., a grand unified theory or quantum gravity).

The *slice* through the filtration at a particular ε-range is the topological analogue of a section of a fiber bundle—it selects a particular projection of the full topological content, and the physics that emerges depends on which slice is taken. The "master equation" is the full adaptive trajectory $\daleth_{\mathcal{F}}^{(\mathrm{adp})}(\mathcal{C})$; the effective field equations at any particular scale are the waypoint constraints restricted to that scale.

5 Dimensional Reduction

5.1 The Dimensional Pathway

The adaptive operator provides a natural pathway for dimensional reduction:

1. **Configuration space** (infinite-dimensional for continuum fields, or $\dim = 4 \times |\Lambda| \times 3$ for SU(2) on a lattice): the raw field data.

2. **Feature space** (d-dimensional): the image of the feature map. For SU(2) with parity-complete map, $d = 12$ (six action densities + six topological charge densities). For language model hidden states, $d \sim 50$ after PCA.

3. **Simplicial complex** (combinatorial): the Rips complex K_ε, a finite simplicial complex whose vertices are the feature-space points.

4. **Sheaf cohomology** ($\mathfrak{g}$-valued, finite-dimensional): the sheaf cohomology groups $H^k(K_\varepsilon; \mathcal{F})$, which are vector spaces over $\mathfrak{g}$.

5. **Persistence diagrams** (2D per feature): each persistent cohomological feature is a point $(b_i, d_i) \in \mathbb{R}^2$.

6. **Waypoint signature** ($(2n_w+3)$-dimensional): the finite-dimensional vector encoding the essential topological content.

7. **Scalar invariants** (1D each): the Gini coefficient, onset scale, total persistence, and topological derivatives are projections of the signature to single numbers.

At each stage, the Čech–de Rham isomorphism (Theorem 1.2) and the bottleneck stability theorem (Theorem 1.1) guarantee that the essential cohomological content is preserved. Information is lost at each compression step, but the *topologically robust* information survives.

5.2 The Two-Dimensional Representation

The most compressed faithful representation of the adaptive operator's output is a two-dimensional curve: the Betti curve $\beta_k(\varepsilon)$ plotted against ε. This curve encodes:

- The onset scale ε^* (where topology first appears).
- The growth rate $d\beta_k/d\varepsilon$ (how fast structure organizes).
- The maximum Betti number and its scale (peak complexity).
- The decay profile (how structure simplifies at large scales).

- The waypoints (extrema of $d\beta_k/d\varepsilon$).

Proposition 5.1 (Two-Dimensional Sufficiency)**.** *The two-dimensional curve $(\varepsilon, \beta_1(\varepsilon))$ is sufficient to detect phase transitions, discriminate topological content, and identify field-equation waypoints, provided the feature map is parity-complete (Construction 2.3).*

The field equations, expressed as waypoint constraints on the Betti curve, are therefore constraints on a two-dimensional object. This is the dimensional reduction: the physics of an infinite-dimensional field configuration is faithfully captured (up to gauge equivalence) by the shape of a curve in $\mathbb{R}^2$.

5.3 Re-expansion: Gauge Orbits as Fibers

The inverse problem—given a waypoint signature, what configurations produce it?—defines the *fiber* over each point in signature space.

Proposition 5.2 (Gauge Orbit Structure)**.** *The fiber $\mathcal{W}^{-1}(w)$ over a waypoint signature w consists of all configurations that are* topologically equivalent *at all scales. For gauge theories, this fiber contains (at minimum) the full gauge orbit of any representative configuration.*

The dimensional reduction from configuration space to signature space is therefore a *quotient by topological equivalence*, which refines the standard quotient by gauge equivalence. Two configurations may be gauge-inequivalent but topologically equivalent (they produce the same persistence data), in which case the waypoint signature captures their shared physical content while discarding gauge artifacts.

6 Applications

6.1 SU(2) Lattice Gauge Theory: Confinement–Deconfinement

Setup. SU(2) pure gauge theory on a $16^3 \times 4$ lattice, coupling β varied from 1.0 to 4.0. The deconfinement transition occurs at $\beta_c \approx 2.30$.

Protocol. For each β:

1. Generate thermalized configurations via heat bath algorithm.
2. Apply the parity-complete feature map $\varphi^{(\mathrm{pc})}$ (Construction 2.3) to obtain a point cloud in $\mathbb{R}^{12}$.
3. Compute the adaptive $\varepsilon_{\max}(\beta)$ as the 95th percentile of pairwise distances.
4. Compute the Betti curve $\beta_1(\varepsilon; \beta)$ over $\varepsilon \in [0, \varepsilon_{\max}(\beta)]$.
5. Extract the onset scale $\varepsilon^*(\beta)$, the maximum topological derivative $\delta_1^{\max}(\beta)$, and the Gini trajectory $d\mathcal{G}_1/d\varepsilon|_{\varepsilon^*}$.

Predictions.

- **Confined phase** ($\beta < 2.30$): Action densities scatter broadly across $\mathbb{R}^{12}$. The point cloud has no natural clustering scale. ε^* is large (topological features appear late). The Betti curve rises gradually. $\mathcal{G}_1$ stays flat (uniform, disordered).
- **Deconfined phase** ($\beta > 2.30$): Action densities cluster near zero (ordered, low-action configurations). The point cloud is compact with well-defined internal structure. ε^* is small (topological features appear early). The Betti curve rises sharply. $\mathcal{G}_1$ is hierarchical (one or two dominant features).
- **Phase boundary** ($\beta \approx 2.30$): $\varepsilon^*(\beta)$ exhibits a discontinuous jump. $\delta_1^{\max}(\beta)$ peaks. The Gini trajectory transitions from flat to hierarchical.

The phase transition is detected entirely from the *shape* of the Betti curve—no Polyakov loop or other order parameter is required.

6.2 Instanton Discrimination

Setup. BPST instanton configurations with topological charge $Q = 0, +1, -1, +2$ on a 12^4 lattice.

Protocol. Apply the parity-complete feature map (which includes $q_{\mu\nu} = \frac{1}{2}\mathrm{ImTr}\, P_{\mu\nu}$) and compute the adaptive Betti curve for each Q.

Predictions.

- **$Q = +1$ vs. $Q = -1$:** The parity-complete feature map distinguishes these because $q_{\mu\nu}$ flips sign. The point clouds in $\mathbb{R}^{12}$ are mirror images, producing different Rips complexes and different persistence signatures.
- **$|Q| = 1$ vs. $|Q| = 2$:** The normalized Betti curve $\beta_1(\varepsilon/\varepsilon_{\max})$ shows a single peak for $|Q| = 1$ and a multi-peaked or broader profile for $|Q| = 2$. The onset scale $\varepsilon^*(|Q|)$ shifts systematically with $|Q|$.
- **Vacuum ($Q = 0$) vs. instanton ($|Q| > 0$):** The vacuum configuration has a qualitatively different Betti curve shape—either trivial (no H_1 features at any scale) or with a distinct onset profile.

The instanton content is encoded in the *shape* of the topological evolution, not in a scalar persistence value at a fixed scale.

6.3 Quantum Harmonic Oscillator: Spectrum as Topology

Setup. A two-dimensional quantum harmonic oscillator with anisotropic potential $V(x, y) = 2kx^2 + \frac{1}{2}ky^2$.

Energy spectrum: $E(n_x, n_y) = \hbar\sqrt{k/m}\,(2n_x + n_y + \frac{3}{2})$, $n_x, n_y = 0, 1, 2, \ldots$

Topological perspective. The energy levels form a lattice in (n_x, n_y) space. The degeneracy structure—which levels coincide, which gaps are largest—is topological.

Apply the adaptive operator to the point cloud of energy levels in $\mathbb{R}^1$ (treating the spectrum as a finite metric space):

- At small ε: each level is isolated ($\beta_0 = N$, all H_0 components).
- As ε increases: nearby levels merge. The onset scales at which mergers occur encode the *gap structure* of the spectrum.
- The longest-lived H_0 features correspond to the *largest energy gaps*—the most physically significant features of the spectrum.

The dimensional reduction is explicit: from the 2D quantum number space (n_x, n_y) to the 1D energy spectrum E, to the 2D persistence diagram that encodes the gap structure.

6.4 Language Model Representations

Setup. Four language models (LFM-1.2B, Qwen2.5-1.5B, SmolLM2-1.7B, TinyLlama-1.1B) probed across layers with structured prompts of varying complexity [11].

Empirical results (validated independently).

- A sharp phase transition in β_1 occurs when prompt complexity crosses a critical threshold: β_1 jumps from 0 to 89 at 247 tokens (LFM-1.2B).
- Cross-model correlation $r = 0.935$ (architecture-universal).
- Gini trajectory is the strongest predictor of output quality: positive trajectory (hierarchification) correlates with accuracy; negative trajectory (flattening) correlates with error.

Connection to the adaptive framework. The prompt complexity parameter τ plays the role of the filtration parameter ε. As τ increases, the hidden-state point cloud reorganizes, and topological features appear abruptly. The phase transition signature is identical in form to the gauge theory case: a discontinuity in onset scale as the control parameter crosses a critical value.

The Industry Benchmark finding [12] provides direct evidence for the waypoint principle: bare prompting (positive Gini trajectory, +0.025/layer, 36.7% accuracy) outperforms the

Jones Framework (negative Gini trajectory, -0.007/layer, 20.0% accuracy) despite producing $10\times$ fewer H_1 loops. The topological *shape* (hierarchical organization) matters more than the topological *count* (number of features). This is exactly the distinction between the Gini curve and the raw Betti number—the curve's shape, not its magnitude, encodes the quality of the system's state.

6.5 Schwarzschild Geometry (Conceptual)

Setup. The Schwarzschild solution describes a non-rotating black hole with event horizon at $r_s = 2GM/c^2$.

Topological waypoint interpretation. Consider the family of spatial slices of the Schwarzschild geometry at decreasing radial coordinate r (with r playing the role of ε):

- $r \gg r_s$: spacetime is approximately flat. The curvature point cloud is diffuse. Topological signature is trivial.
- $r \to r_s$: tidal forces grow, curvature concentrates, the point cloud develops sharp structure. Topological features appear.
- $r = r_s$: the event horizon is a topological waypoint—a qualitative change in the causal structure (space and time exchange roles).
- $r < r_s$: the topology has fundamentally changed.

The Einstein field equations, in this framework, are the constraints that determine *at which* r the waypoint occurs (answer: $r_s = 2GM/c^2$) and what the topology looks like on either side. The field equation is a waypoint constraint: a condition on the topological evolution curve that selects the physical solution.

7 The Continuous–Discrete Bridge

7.1 Discreteness as Fundamental

The Čech–de Rham isomorphism (Theorem 1.2) is traditionally read as: "discrete cohomology approximates continuous cohomology." We propose the converse reading: *continuous field theory is the macroscopic limit of discrete topological dynamics.*

This inversion has a specific consequence. Algebraic obstructions that exist in the smooth category—such as the Nguyen–Polya result [2] showing that no smooth Shiab operator exists on the Spin(14) bundle of Geometric Unity—may not exist in the discrete category. The obstruction is a property of smooth differential forms on smooth manifolds; it does not necessarily constrain combinatorial cochains on simplicial complexes.

Proposition 7.1 (Dissolution of Smooth Obstructions)**.** *Let $\mathcal{O}$ be an algebraic obstruction to the existence of a smooth map $\daleth : \Omega^2(Y;\mathrm{Ad}) \to \Omega^0(Y;\mathrm{Ad})$ on a smooth manifold Y. If the obstruction $\mathcal{O}$ depends essentially on the smooth structure of Y (e.g., on the existence of smooth partitions of unity, or on the representation theory of the smooth structure group), then $\mathcal{O}$ may fail to obstruct the corresponding discrete map $\daleth_{\mathcal{F}} : C^2(K;\mathcal{F}) \to C^0(K;\mathcal{F})$ on a simplicial complex K with sheaf $\mathcal{F}$.*

This is not a proof that the Spin(14) obstruction dissolves in the discrete category—it is a statement that the obstruction's applicability to discrete complexes must be independently verified, not assumed. The discrete topological framework occupies a different mathematical category from the smooth geometric one, and obstructions do not automatically transfer between categories.

7.2 The Fiber Bundle Perspective

The adaptive filtration has a natural interpretation in the language of fiber bundles:

- **Base space:** The filtration parameter ε (or equivalently, the observation scale).
- **Fiber:** The sheaf cohomology group $H^k(K_\varepsilon; \mathcal{F}_\varepsilon)$ at scale ε.
- **Total space:** The family $\{H^k(K_\varepsilon; \mathcal{F}_\varepsilon)\}_{\varepsilon \geq 0}$, which is a (generalized) vector bundle over the base $[0, \varepsilon_{\max}]$.
- **Connection:** The persistent homology maps $H^k(K_\varepsilon) \to H^k(K_{\varepsilon'})$ for $\varepsilon \leq \varepsilon'$, which describe how cohomological features are transported across scales.

In string theory, the "master geometry" is a fiber bundle (e.g., a Calabi–Yau fibration) whose topology determines the low-energy physics. The adaptive topological framework provides an analogous structure: the "master geometry" is the total space of persistent sheaf cohomology, and the "slices" at different ε values yield different effective field theories.

The key difference: in string theory, the fiber is a smooth Calabi–Yau manifold (6 real dimensions, hundreds of topological parameters). In the adaptive framework, the fiber is a sheaf cohomology group (finite-dimensional, computable). The trade-off is generality for computability.

8 Predictions and Validation Program

The framework makes the following concrete, testable predictions:

1. **SU(2) phase transition (onset discontinuity):** The onset scale $\varepsilon^*(\beta)$ exhibits a discontinuous jump at $\beta_c \approx 2.30$ on a $16^3 \times 4$ lattice.

2. **Instanton discrimination (profile shape):** The normalized Betti curve $\beta_1(\varepsilon/\varepsilon_{\max})$ has qualitatively different shapes for $|Q| = 0, 1, 2$, and the parity-complete feature map distinguishes $Q = +1$ from $Q = -1$.

3. **Architecture universality (cross-model correlation):** The topological phase transition in LLM hidden states is universal across architectures ($r > 0.9$). *[Already validated: $r = 0.935$ across four architectures.]*

4. **Shape over count (Gini trajectory):** Positive Gini trajectory (hierarchification) correlates with higher reasoning accuracy across prompt types and model scales. *[Already validated: bare prompting's $+0.025$ vs. Jones Framework's -0.007 on SmolLM2-1.7B.]*

5. **Sheaf Laplacian kernel (field equations):** On-shell SU(2) configurations have a larger $\dim\ker(L_{\mathcal{F}})$ than off-shell configurations at the critical filtration scale ε_c.

6. **Waypoint universality:** Phase transitions in gauge theory, LLM representations, and quantum spectra all exhibit the same qualitative pattern: a discontinuity in onset scale as a control parameter crosses a critical value.

7. **Two-dimensional sufficiency:** The Betti curve $(\varepsilon, \beta_1(\varepsilon))$ is sufficient to discriminate on-shell from off-shell configurations in SU(2) gauge theory.

Predictions 3 and 4 have been validated. Predictions 1, 2, 5, 6, and 7 are computationally testable with existing tools (Ripser for persistent homology, PyTorch Geometric or custom code for sheaf Laplacians, standard lattice gauge theory simulation codes for SU(2)).

9 Open Questions

1. **Inversion problem.** Given a waypoint signature, how many gauge-inequivalent configurations produce it? If the answer is "one" (up to gauge equivalence), the signature is a complete invariant.

2. **Continuum limit.** Does the adaptive waypoint formulation converge to a well-defined continuum theory as lattice spacing $a \to 0$? The Čech–de Rham isomorphism guarantees cohomological equivalence, but the persistence diagrams may develop singularities in the limit.

3. **Spin(14) obstruction in the discrete category.** Does the Nguyen–Polya obstruction survive in the category of cellular sheaves on simplicial complexes? If not, the adaptive sheaf-valued operator may provide a constructive realization of the Shiab operator in Geometric Unity.

4. **Scale dependence in LLMs.** Does the Gini trajectory remain the dominant predictor of reasoning quality at 7B+ and 70B+ parameter scales?

5. **Hardware.** The sheaf Laplacian computation on Rips complexes is parallelizable and local. Custom hardware that natively computes persistent sheaf cohomology could accelerate the pipeline by orders of magnitude relative to Boolean logic simulation.

6. **Quantum gravity.** If the master field equation is fundamentally discrete (with continuous GR as a macroscopic limit), the waypoint constraints at the smallest filtration scales may encode Planck-scale physics. The adaptive framework provides a concrete computational protocol for exploring this regime.

10 Conclusion

We have constructed a mathematical framework—the Adaptive Topological Operator with sheaf-valued persistent homology—that provides a unified language for expressing field equations across physical domains.

The framework rests on three pillars:

Adaptive filtration. The filtration parameter ε is treated as a temporal/scale variable, not a static threshold. The fundamental observable is the *trajectory* of topological evolution across scales, not the topology at any single scale.

The Čech–de Rham bridge. The isomorphism between smooth de Rham cohomology and discrete Čech cohomology guarantees that persistent homology on Rips complexes computes the same cohomological invariants as continuous differential geometry. The discrete computation is not an approximation—it is an exact computation in a different (but isomorphic) category.

Sheaf-valued homology. Attaching Lie algebra fibers to the Rips complex via cellular sheaves upgrades the output from scalar invariants (Betti numbers) to algebraic-valued sections (elements of $\mathfrak{g}$). This resolves the category mismatch between topological data analysis and gauge field theory, and enables the sheaf Laplacian kernel to encode field equation solutions.

The central claim is the *waypoint principle*: the field equations of a physical theory are geometric constraints on the topological evolution trajectory. They select which trajectories (among all possible topological evolutions under adaptive filtration) correspond to physical configurations.

This principle has been empirically validated in the domain of language model representations, where the Gini trajectory of the topological evolution predicts reasoning quality with architecture-universal consistency ($r = 0.935$ across four models). Its validation in lattice gauge theory (SU(2) phase transition detection via onset-scale discontinuity, instanton discrimination via Betti curve profile) is the immediate computational priority.

The deepest implication is methodological: *topology at multiple scales is more fundamental than geometry at a single scale.* The physics of a system is not encoded in its metric properties at one resolution but in how its topological structure reorganizes across all resolutions. The adaptive operator is the instrument for reading this multi-scale structure, and the waypoint constraints it reveals are the field equations written in the native language of topology.
